GRAVITATIONAL LENSING

13 - MICROLENSING RATES - MULTIPLE POINT LENSES

Massimo Meneghetti AA 2018-2019

OPTICAL DEPTH (FROM THE LAST LESSON)

 $\tau(D_{\rm S}) = \frac{1}{\Omega} \int_0^{D_{\rm S}} [\Omega D_{\rm L}^2 n(D_{\rm L})] (\pi \theta_E^2) dD_{\rm L}$

$$\tau(D_{S}) = \frac{4\pi G}{c^{2}} \int_{0}^{D_{S}} \rho(D_{L}) D_{L}^{2} \frac{D_{LS}}{D_{L}D_{S}} dD_{L}
= \frac{4\pi G}{c^{2}} \int_{0}^{D_{S}} \rho(D_{L}) D_{L} \frac{D_{S} - D_{L}}{D_{S}} dD_{L}
= \frac{4\pi G}{c^{2}} \int_{0}^{D_{S}} \rho(D_{L}) \frac{D_{L}}{D_{S}} \left(1 - \frac{D_{L}}{D_{S}}\right) D_{S} dD_{L}$$

with the substitution $x = D_L/D_S$, $dx = dD_L/D_S$

$$\tau(D_{S}) = \frac{4\pi G}{c^{2}} D_{S}^{2} \int_{0}^{1} \rho(x) x(1-x) dx$$

The optical depth gives the probability that a source is (micro-)lensed at any instant. The next question is: how many events will we detect by monitoring a certain number of stars during a time interval?

To answer this question, we have to consider the relative motion of sources and lenses, which determines the timescale of events.

It is easier to think in terms of static sources behind moving lenses.

We also assume that the lenses move with the same transverse velocity.

$$dA = 2r_E v dt = 2r_E^2 \frac{dt}{t_E}$$

Multiplying by the number of lenses and integrating over distance we obtain the area useful for microlensing during the time dt. Dividing by the solid angle, we obtain a probability that a source undergoes a micro lensing event in the time dt:

$$d\tau = \frac{1}{\Omega} \int_0^{D_{\rm S}} n(D_{\rm L}) \Omega dA dD_{\rm L} = 2 \int_0^{D_{\rm S}} n(D_{\rm L}) r_E^2 \frac{dt}{t_E} dD_{\rm L}$$

If we monitor N stars, the number of events expected per unit time will be:

$$\Gamma = \frac{d(N_{\star}\tau)}{dt} = \frac{2N_{\star}}{\pi} \int_{0}^{D_{\mathrm{S}}} n(D_{\mathrm{L}}) \frac{\pi r_{E}^{2}}{t_{E}} dD_{\mathrm{L}}$$

If we assume that all Einstein crossing times are identical:

$$\Gamma = \frac{2N_{\star}}{\pi t_E} \tau$$

As an order of magnitude:

$$\Gamma \approx 1200 \text{yr}^{-1} \frac{N_{\star}}{10^8} \frac{\tau}{10^{-6}} \left(\frac{t_E}{19 \text{days}} \right)^{-1}$$

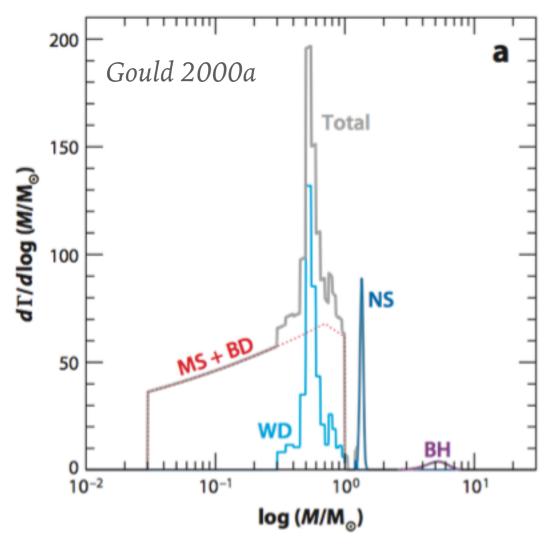

For comparison: OGLE IV detected 1500-2000 candidates/year in the 2011-2017 campaigns.

Note that:
$$\Gamma \propto t_E^{-1} \propto M^{-1/2}$$

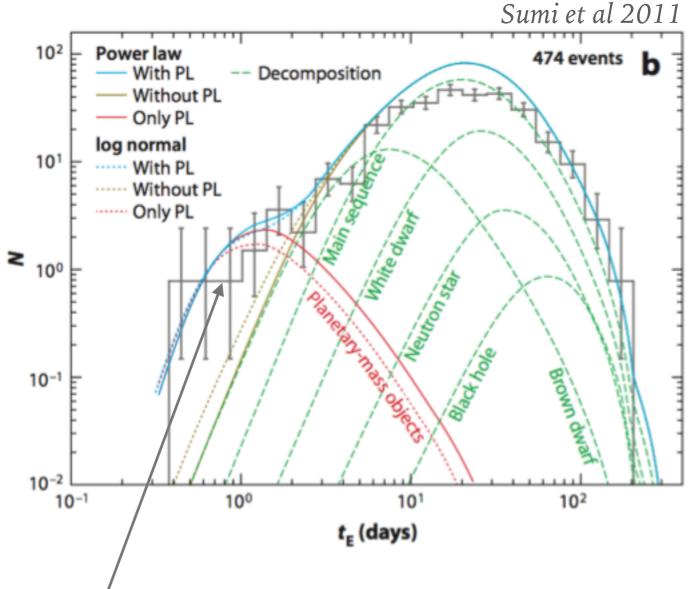

We can use the distribution of event timescales to probe the kinematics of the Milky Way and the stellar populations in the galaxy.

PROBING THE STELLAR POPULATIONS WITH MICROLENSING

Gaudi, 2012, Ann. Rev. Astron. Astrophys. 50, 411

Theoretical estimate of the rate of microlensing events towards the galactic bulge

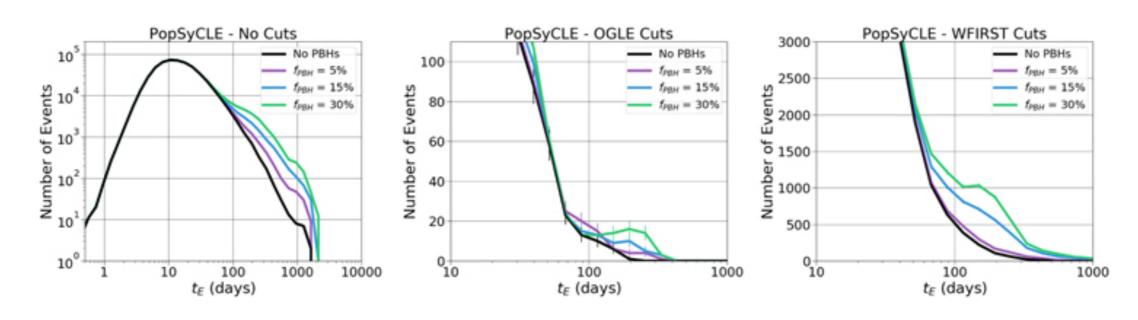

Distribution of microlensing event timescales observed by the MOA collaboration (2006-2007)

SOME IMPORTANT FACTS

- ➤ several collaborations have implemented the microlensing idea (proposed by B. Paczynski). These groups have monitored the galactic bulge and the Magellanic Clouds searching for microlensing events
- ➤ the relatively high rate of detections favored a barred model of the galaxy
- ➤ Towards the Magellanic Clouds, no 'short' events (timescales from a few hours up to 20 days) have been seen by any group. This places strong limits on 'Jupiters' in the dark halo: specifically, compact objects in the mass range 10⁻⁶–0.05 solar masses contribute less than 10% of the dark matter around our Galaxy. This is a very important result, as these objects were previously thought to be the most plausible form of baryonic dark matter, and (for masses below 0.01 solar masses) they would have been virtually impossible to detect directly.

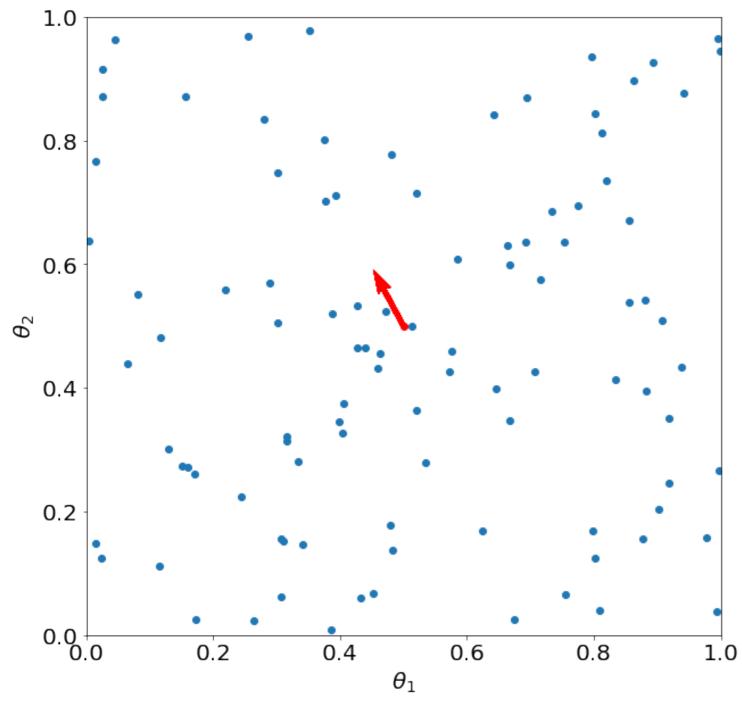

SOME IMPORTANT FACTS

- ➤ In general: all detections of microlensing events are most likely caused by known stellar populations. BHs can contribute to 2% of the total mass of the halo.
- ➤ The recent detection of GW from merging BHs with intermediate masses has revived the idea of BHs as dark-matter candidates. For such lenses, the time scale of the events would be large so that past microlensing events may not have detected them.

Lu et al. 2019

MULTIPLE POINT MASSES

We conceder a system of N point masses at the same distance D_L .

As seen, a light ray crossing the lens plane at the portion θ will experience the deflection

$$\hat{\alpha}(\overrightarrow{\theta}) = \frac{4G}{c^2 D_L} \sum_{i=1}^{N} \frac{M_i}{|\overrightarrow{\theta} - \overrightarrow{\theta}_i|^2} (\overrightarrow{\theta} - \overrightarrow{\theta}_i)$$

MULTIPLE POINT MASSES

- compared to an individual point mass, the spatial symmetry is broken
- ➤ The mass scale of the system is the total mass=sum of the individual masses
- ➤ We may use this mass to define an equivalent Einstein radius and use it to scale all angles

MULTIPLE POINT MASSES

$$M_{tot} = \sum_{i=1}^{N} M_i$$
 $m_i = M_i/M_{tot}$

$$\vec{\alpha}(\vec{\theta}) = \sum_{i=1}^{N} \frac{D_{\mathrm{LS}}}{D_{\mathrm{L}}D_{\mathrm{S}}} \frac{4GM_i}{c^2} \frac{(\vec{\theta} - \vec{\theta}_i)}{|\vec{\theta} - \vec{\theta}_i|^2} \frac{M_{tot}}{M_{tot}} = \sum_{i=1}^{N} m_i \frac{\theta_E^2}{|\vec{\theta} - \vec{\theta}_i|^2} (\vec{\theta} - \vec{\theta}_i)$$

dividing by θ_E :

$$\vec{\alpha}(\vec{x}) = \sum_{i=1}^{N} \frac{m_i}{|\vec{x} - \vec{x}_i|^2} (\vec{x} - \vec{x}_i)$$

$$\vec{y} = \vec{x} - \sum_{i=1}^{N} \frac{m_i}{|\vec{x} - \vec{x}_i|^2} (\vec{x} - \vec{x}_i)$$

COMPLEX LENS EQUATION (WITT, 1990)

$$\vec{y} = \vec{x} - \sum_{i=1}^{N} \frac{m_i}{|\vec{x} - \vec{x}_i|^2} (\vec{x} - \vec{x}_i)$$

$$z = x_1 + ix_2 \qquad \qquad z_s = y_1 + iy_2$$

$$\alpha(z) = \sum_{i=1}^{N} m_i \frac{(z - z_i)}{(z - z_i)(z^* - z_i^*)} = \sum_{i=1}^{N} \frac{m_i}{z^* - z_i^*}$$

$$z_s = z - \sum_{i=1}^{N} \frac{m_i}{z^* - z_i^*}$$

COMPLEX LENS EQUATION (WITT, 1990)

➤ Thus:

$$z_s = z - \sum_{i=1}^{N} \frac{m_i}{z^* - z_i^*}$$

➤ Taking the conjugate:

$$z^* = z_s^* + \sum_{i=1}^{N} \frac{m_i}{z - z_i}$$

➤ We obtain z* and substitute it back into the original equation, which results in a (N²+1)th order complex polynomial equation

➤ This equation can be solved only numerically, even in the case of a binary lens
